Plasma renin concentration in the measurement of plasma renin substrate in man. The stability of plasma renin substrate (PRS) was studied during simulated clinical conditions. In a first series of experiments, PRS was added to plasma samples collected from 3 volunteers in a polypropylene tube, placed at 4 degrees C and transferred to a freezer compartment at -80 degrees C as quickly as possible. In a second series, plasma was either added to a chilled heparinized vessel and immediately centrifuged, or centrifuged and transferred to a freezer. In a third series of experiments, 100 microliters of heparinized plasma was transferred to a polypropylene tube and immediately centrifuged and stored at -80 degrees C. In a fourth series of experiments, plasma was mixed with PRS and stored at -80 degrees C. After different periods of storage, the samples were assayed for PRS activity with a radioimmunoassay and for total renin activity with a radioreceptor assay. The concentration of PRS was determined from the values of total renin activity in the presence and absence of PRS. In the first series of experiments, the PRS activity was stable for at least 12 months, while the total renin activity was stable for only 6 months. In the second series, the PRS activity was stable for at least 6 months, while the total renin activity decreased after 2 months. In the third series of experiments, the total renin activity was stable for at least 6 months, while the PRS activity decreased by about 50% after 5 months. In the fourth series of experiments, the PRS activity was stable for at least 4 weeks, while the total renin activity was stable for up to 15 weeks. Lyrics 82157476af
